Abstract

Background and Aims: Primary infections of rubella and human cytomegalovirus (HCMV) can lead to severe complications in pregnancy. The screening of Rubella and HCMV in pregnant women is not routinely carried out in Iran. This cross sectional study aimed to investigate the seroprevalence of HCMV and rubella infections in neonates with and without congenital defects.

Materials and Methods: This study was carried out in four provinces of Iran including Mazandaran, Hormozgan, Yazd, and Kerman. Demographic data were collected through questioners and samples were taken from umbilical cord bloods of 182 and 387 neonates with and without congenital defects, respectively. To detect HCMV and rubella infections we measured IgG and IgM antibodies using ELISA and HI which were used for measurement of anti-rubella total antibodies.

Results: The prevalence of anti-HCMV IgG antibody was found to be around 90%, while 7.14% of neonates with congenital defects were positive for anti-HCMV IgM antibody compared to 2.84% of control group ($p < 0.05$). Anti-rubella total antibody was found in 85% and rubella IgM seropositivity rate was 0.5%.

Conclusion: Although not for rubella, the significant correlation found between HCMV IgM positivity and congenital defects highlights the importance of these infections during pregnancy. Routine screening for rubella and HCMV should be introduced for pregnant women in our setting. Although mass rubella vaccination program is introduced in our system since 2004, preventive measures should be taken to decrease the mortality and morbidity related to primary HCMV infections.

Keywords: Rubella; congenital malformations; maternal antibodies; neonates

Introduction

Rubella and HCMV infections are major public health concerns when occurring early in pregnancy. Severity of damage or the outcome of infections almost depends on the time at which infection occurs. Maternal infection during the first weeks of gestation

results in nearly all fetuses to become infected, leading to the fetal death, miscarriage or development of congenital defects such as cataracts, mental retardation and hearing loss (1, 2).

Rubella infection is a common cause of exanthematous disease which predominantly occurs in childhood. The seroprevalence of rubella virus varies and the seropositivity of 54.1% to 95.2% has been reported from different studies conducted in different countries (3-8).

HCMV is endemic all over the world and its prevalence varies from 60% to 100% based on different populations and countries (9). HCMV infection is usually asymptomatic in adults but it is a main public health concern when it occurs during pregnancy. Primary HCMV infection occurs in 0.15 to 2.0% of all pregnancies and in up to 40% of these cases the virus may be transmitted to the fetus whereas this ratio is less than 2% after a recurrent maternal infection with HCMV (10, 11). At birth, perinatal HCMV infection results in symptomatic congenital disease in up to 15% and the majority of these infections are asymptomatic. However, 10 to 15% of those born with asymptomatic congenital HCMV were found to develop significant clinical sequelae (10, 12). As previously indicated, HCMV and rubella virus are increasingly being recognized as important causes of congenital infection. However, a previous exposure to rubella virus actually prevents it from crossing the placenta via protective antibodies produced against the virus; whereas, in HCMV, intrauterine transmission to the fetus can occur irrespective of prior maternal exposure. Surveys correlating congenital malformations and viral agents particularly rubella and HCMV are limited in our country. The aim of our study was to investigate the prevalence of rubella and HCMV antibodies in cord blood samples taken from newborns with and without congenital defects in different parts of Iran.

Methods

This was a cross-sectional study conducted at virology center of school of public health in Tehran University of Medical Sciences (TUMS). Umbilical cord blood samples were collected from 569 neonates with and without congenital defects (182 abnormal and 387 healthy considered as case and control, respectively) attended at the maternity unit of the main state hospitals in four provinces of Iran including Mazandaran, Hormozgan, Yazd, and Kerman. This study was conducted between January 2002 and January 2004

before mass vaccination for rubella and measles in Iran. Demographic data were collected through questioners. In few cases, the gender section of questioners was left empty therefore we categorized them as unknown group. Sera were collected and stored at -20 and -80 until used. Sera were then tested for anti-rubella and anti-HCMV IgM and IgG antibodies using enzyme immunoassay (Biochem-kit, Italy). All suspected results were re-tested by another commercial kit (Behring, German).

Haemagglutination Inhibition Test (HI) was also used to investigate total Rubella antibodies. For the purpose of our study dilutions of 1/8, 1/16, and 1/32 were used. A titer of 1/32 was considered as protective and titer of less than 1/8 considered as no immunity. Titers between 1/8 and 1/32 were repeated and considered positive if only the repeated test was above 1/8.

Statistical Package for Social Sciences (SPSS, version 10.0) software was used to analyse the data. The p-value less than 0.05 was considered statistically significant.

Results

To determine the seropositivity rates of anti-total rubella and anti-HCMV IgG antibodies, cord blood samples were taken from 387 healthy and 182 neonates with congenital defects. Table 1 shows the frequency and distributions of newborns (case and control) according to demographic characteristics such as gender, location, and age. As indicated in table 2, around 90% of neonates with and without congenital defects were shown to be positive for anti-total rubella antibodies. Accordingly, 86.56% of cases and 84.07% of controls were positive for anti-HCMV IgG antibodies and statistically there was no significant difference between cases and controls. However, looking at anti-HCMV IgM antibodies 7.14% of neonates with congenital defects were found to be positive compared to 2.4% of healthy group. The frequency of anti-HCMV IgM antibodies was significantly higher in case group than controls ($P= 0.021$).

Table 1. Demographic characteristics and distribution of umbilical cord blood samples taken from neonates with and without congenital defects.

Characteristic	Case		Control		Total	
	No.	%	No.	%	No.	%
Province						
Mazandaran	45	24.7	88	22.7	133	23
Hormozgan	97	53.3	191	49.4	288	51
Yaz	20	11	63	16.3	83	15
Kerman	20	11	45	11.6	65	11
Age (Mother)						
13-20	56	30.8	89	23	145	25.5
20-27	72	39.6	168	43.4	240	42
27-34	41	22.5	102	26.4	143	25.5
≥ 34	13	7	28	7	41	7
Gender						
Female	78	42.86	168	43.41	246	43
Male	83	45.60	200	51.68	283	50
Unknown	21	11.54	19	4.91	40	7

We then analysed data based on gender to check if there is any correlation between CMV IgM seropositivity and gender. Indeed, as shown in table 3 the seropositivity of HCMV IgM was significantly higher in girls born with congenital defects than those without defects (11.54% vs. 3.57%; $P= 0.019$). Comparing boys with and without congenital defects we could not find such a significant difference. Next we did check the samples for anti-rubella IgM antibodies and none of cases were found to be positive; however, to our surprise two neonates (one girl and one boy) from control group became positive for anti-rubella IgM antibodies.

Discussion

Cytomegalovirus and rubella are major public concern in terms of prenatal and perinatal

infections as these infections can result in main clinical complications on pregnancy for both maternal and fetal health (2, 13).

Human cytomegalovirus is a ubiquitous virus which affects fetus during pregnancy. Although not protective, maternal antibodies do reduce both the rate of virus transmission and the severity of damages to the fetus (14). In our country, except one study where the HCMV IgG seropositivity has been reported to be 72.1% (15) the prevalence of HCMV has been shown between 90 to 97% based on different studies (16). In our study, which was performed on umbilical cord bloods, the HCMV seropositivity rate was found to be around 85%. Our result was similar to the results obtained from other countries in Middle East or Asia such as Turkey (17), Saudi Arabia (18), and Singapore (19).

Table 2. Frequency of rubella and HCMV antibodies in neonates with and without congenital defects.

Characteristic	Anti-rubella total antibodies		Anti-HCMV IgG antibodies	
	Case %	Control %	Case %	Control %
Province				
Mazandaran	91.1	89.8	75.6	72.7
Hormozgan	89.7	92.1	87.7	93.7
Yaz	85	90.5	75	82.5
Kerman	85	88.9	95	88.9
Age (Mother)				
13-20	87.5	87.5	82.1	88.8
20-27	87.5	90.5	84.7	88.1
27-34	92.7	93.1	82.9	83.3
≥ 34	93.5	97	92.5	82
Gender				
Female	88	90.5	83.13	88
Male	88.5	91.7	88.46	85.12
Unknown	95.24	89.5	71.43	84.21

Although 7.14% of cases and 2.84% of controls were IgM positive for HCMV, it appears that the rate of IgM seropositivity for HCMV in our populations might be even higher as it has been already shown that in a percentage of cases IgM titer can be undetectable (14). In most cases, congenital infections caused by HCMV are shown to be subclinical at birth (12) that can be a reason why we found anti-HCMV IgM antibodies in 11 neonates (2.84%) who were in control group and showed no clinical sign. It is worth to note that in some cases although there is no sign of congenital inclusion disease (CID) virus reactivation cannot be underestimated or ignored.

In the current study, the prevalence of rubella in mothers was shown to be around 90%, similar to the previous studies performed in our

society on different age groups where the immunity rate against rubella has been reported to be 85% to 95% (20-22). Looking at anti-rubella IgM antibodies, only two samples taken from healthy group were positive. The absence of IgM titer or inability to detect in case group can be explained by small sample size, reduction of IgM titer during freeze and thaw process. As indicated, anti-rubella IgM only detected in two control samples. This may reflect the fact that like HCMV, rubella has delayed clinical symptoms such as deafness which may not be revealed even till 1 year after birth, indicating the possibility of not being considered these two samples as control group. The current study had some limitations such as the lack of follow-up for these women or children in order to document seroconversion and to detect subclinical infections which reveal later. Inability to use

Table 3. Frequency of anti HCMV IgM antibodies in neonates with and without congenital defects.

Characteristic	Anti-HCMV IgM antibodies		P value

Male	4.82(4)	2.5 (5)	p= 0.25
Unknown	0	0	-

polymerase chain reaction (PCR) to detect viral DNA or RNA can be another limitation of this study.

Conclusion

Although not for rubella, the significant correlation found between HCMV IgM positivity and congenital defects highlights the importance of these infections during pregnancy. Routine screening for rubella and HCMV should be introduced for pregnant women in our setting. Although mass rubella vaccination program was introduced in our system, preventive measures should be taken to decrease the mortality and morbidity related to primary H CMV infections.
